ABSTRACT

Paleoclimate model simulations provide reference data to help interpret the geological record and offer a unique opportunity to evaluate the performance of current models under diverse boundary conditions. Here, we present a database of 35 climate model simulations of the warm early Eocene Climatic Optimum (EECO; ~ 50 million years ago) and corresponding preindustrial reference experiments. To streamline the use of the data, we apply standardised naming conventions and quality checks across eight modelling groups that have carried out coordinated simulations as part of the Deep-Time Model Intercomparison Project (DeepMIP). Gridded model fields can be downloaded from an online repository or accessed through a new web application that provides interactive data exploration. Local model data can be extracted in CSV format or visualised online for streamlined model-data comparisons. Additionally, processing and visualisation code templates may serve as a starting point for advanced analysis. The database and online platform aim to simplify accessing and handling complex data, prevent common processing issues, and facilitate the sharing of climate model data across disciplines.

Background & Summary

Past climate changes provide an opportunity to better understand how key components of the climate system might change under anthropogenic greenhouse gas emissions and thus help constrain future climate change¹. Comparisons with paleoclimate data allow us to evaluate climate models under atmospheric CO₂ scenarios similar to those possible in the near future. Furthermore,

34 these paleoclimate model simulations provide global, physically consistent reference data to support the interpretation of
35 paleoclimatic data across a wide range of disciplines, e.g. in geology, biology, and geochemistry.

36

37 One of the most well-studied past time intervals with respect to model-data comparison is the early Eocene Climatic
38 Optimum (EECO; ~53.3 to 49.1 million years ago²) as it provides an analogue for future very high emission scenarios³. It was
39 characterised by atmospheric CO₂ concentrations of ~1,500 ppm⁴ and global mean surface temperatures (GMSTs) 10 to 16 °C
40 warmer than pre-industrial⁵. Several modelling studies have focused on improving our understanding of the mechanisms and
41 implications of EECO warmth^{6–10} and ultimately motivated the formulation of the Eocene Modelling Intercomparison Project
42 (EoMIP)¹¹. While limited due to its opportunistic design, EoMIP nonetheless highlighted the possibility of using multi-model
43 ensembles to systematically assess model-model and model-data differences in our understanding of Eocene climate.

44

45 Building on this potential, DeepMIP – the Deep-Time Model Intercomparison Project – was designed to provide a consistent
46 framework to carry out coordinated EECO model experiments¹². Eight modelling groups performed a total of 35 model simula-
47 tions using the same paleogeographic and vegetation boundary conditions at a range of atmospheric CO₂ concentrations (Table
48 1). These new simulations showed more consistent global mean surface temperatures across the ensemble and larger climate
49 sensitivities compared to the EoMIP results¹³. The coordinated experiment set-up allowed a separation of the relative influence
50 of changes in CO₂ concentrations and non-CO₂ boundary conditions (i.e. removal of land ice and prescribed vegetation) on the
51 simulated surface temperatures. Non-CO₂ boundary conditions alone lead to 3–5 °C overall warming and contribute substantially
52 to the reduced meridional temperature gradient, while higher CO₂ levels drive global mean warming due to decreases in
53 atmospheric emissivity. Importantly, three models (CESM1.2-CAM5, GFDL-CM2.1 and NorESM1-F) were able to produce
54 a global surface temperature distribution similar to paleoclimate data at CO₂ concentrations consistent with the geological record.

55

56 The DeepMIP-Eocene ensemble has already been used in multiple studies, analysing specific aspects of the Eocene
57 climate in more detail, e.g. the meridional temperature gradient¹⁴, the surface to deep ocean temperature relationship¹⁵,
58 ocean circulation¹⁶, sea ice¹⁷, hydroclimate^{18–20}, and the impact of mountains^{21,22}. We anticipate continued interest in the
59 DeepMIP-Eocene model data, both for model intercomparisons and for model-data syntheses, and aim to document the design
60 of the database and streamline access to improve future re-use of the data. Although the use of large model ensembles is
61 helpful in quantifying the influence of uncertainties in boundary conditions and limitations in model performance on the

62 simulated Eocene climate, it also presents a technical hurdle in accessing and fully utilising the available data. The use of
63 model-specific data standards, post-processing workflows and variable naming schemes can make the analysis and comparison
64 of multi-model ensembles a tedious process or even lead to processing errors. The need for significant data processing expertise
65 can therefore limit the benefits and wider use of these important data, particularly in non-modelling paleoclimatology disciplines.

66

67 Here, we build on the DeepMIP framework to address these issues and present standardised, quality-checked EECO model
68 output to facilitate multi-model processing and analysis, both for model intercomparisons and model-data comparisons. We
69 have reprocessed the output of a total of 26 EECO simulations at CO₂ concentrations between ×1 and ×9 pre-industrial
70 levels, together with their nine pre-industrial reference experiments, to generate a database of common climate variables with
71 consistent temporal averaging, variable names and units across the ensemble. We follow the CMIP convention for variable
72 names and units as closely as possible to take advantage of existing processing workflows, and use the ensemble spread to
73 quantify the internal consistency of the output fields.

74

75 We provide two complementary ways of accessing the database, tailored to the most likely future use cases. First, the
76 entire database is stored as global, gridded netCDF (network Common Data Form) files in the Centre for Environmental Data
77 Analysis (CEDA) Archive and can be downloaded as individual files or in batch mode. Combined with the consistent DeepMIP
78 naming convention, this provides a more traditional, scriptable starting point for further analysis. Second, we present an
79 interactive web application to facilitate model-data comparisons of EECO surface temperatures and precipitation. This is a very
80 common use case for paleoclimate model data, but also involves multiple processing steps and potential pitfalls, especially
81 when working with a large model ensemble. The web application automatically calculates paleolocations for a single site or
82 a list of present-day locations, extracts the corresponding model data from the various model grids and plots a summary of
83 the results. The resulting data can be exported for further offline analysis, while the underlying Python code can be used as a
84 starting point for custom analysis.

85

86 The database and tools provided are designed to enable data access for non-programmers and to streamline analysis for
87 more advanced users to routinely evaluate existing and emerging paleoclimate data against the full DeepMIP-Eocene model
88 ensemble. This will help to bridge the gap between modelling and data communities to ultimately advance our understanding of
89 early Eocene climate and could potentially serve as a reference framework for similar projects of other geological time periods

90 in the future.

91 Methods

92 DeepMIP-Eocene experiments

93 All EECO simulations that follow the DeepMIP-Eocene experimental design protocol¹² and are completed by September
94 2023 form the input data for version 1.0 of the database (Table 1). These simulations are identical to those described in
95 the DeepMIP overview paper¹³, with the exception of the new MIROC $\times 1$ and $\times 2$ experiments. The DeepMIP framework
96 provides standardised model boundary conditions and experimental designs to allow a coordinated model intercomparison
97 of the simulation results. All groups have used one of the two reference paleogeographic reconstructions^{23,24} interpolated
98 to their respective model grids. Prescribed vegetation and river runoff follow a published reconstruction²³, while globally
99 homogeneous soil parameters based on the global mean of the respective pre-industrial simulation were used. All groups
100 provided a pre-industrial reference simulation and performed a series of EECO experiments, differing only in the concentration
101 of atmospheric CO₂, summarised in Table 2. Other greenhouse gas concentrations and the solar constant were held constant at
102 their pre-industrial levels.

103

104 A complete overview of the modelling framework is given in the DeepMIP experimental design paper¹², and detailed
105 descriptions of its implementation in the individual models can be found in the analysis of the large-scale climatic features¹³.
106 We also provide a full description of each model setup based on their published method sections¹³ as a README file in the
107 database itself. This is intended to make the downloaded files self-describing and to allow dynamic addition of new experiments
108 and models in the future. In the following, for each model included in version 1.0 of the database, we provide a brief summary
109 of the initialisation and spin-up strategies, as this step required individual decisions by each modelling group. If applicable, we
110 also point out any other deviations from the DeepMIP protocol above.

111 CESM

112 Ocean temperatures and salinities in all Eocene simulations are initialised from the same Palaeocene–Eocene Thermal Maximum
113 (PETM; ~55 million years ago) experiment using a previous version of CESM^{25,26}. The $\times 1$ simulation was integrated for a
114 further 2600 years, while all other experiments were run for 2000 years.

115 **COSMOS**

116 The $\times 3$ integration was initialised with a homogeneous temperature and salinity of 10 °C and 34.7 psu, respectively, and
117 integrated for an initial 1000 years, after which the $\times 1$ and $\times 4$ simulations were branched. After an initial 8000 years with
118 transient orbital parameters, a constant, pre-industrial orbital configuration was used for the final 1500 years of all simulations.
119 Instead of using the proposed river routing scheme²³, the simulations use a hydrological discharge model that follows the model
120 orography²⁷.

121 **GFDL**

122 The $\times 1$, $\times 2$, $\times 3$, and $\times 4$ simulations were started from an idealized ocean temperature profile and a globally homogeneous
123 salinity of 34.7 psu. After 1500 and 2000 years of integration, an acceleration technique was applied. Specifically, the linear
124 temperature trends of the last 100 years for each model level below 500 m calculated and the temperature then extrapolated by
125 a 1000 years following this trend. After the second application of this technique at year 2000, the model was run out normally
126 for a further 4000 years for a total of 6000 years. The $\times 6$ simulation was initialised with a globally uniform temperature of
127 19.32 °C and continuously integrated for 6000 years.

128 **HadCM3**

129 Initial ocean temperatures for HadCM3BL were derived from an idealised temperature profile with lowered, CO₂ dependent
130 deep ocean temperatures based on previous Eocene simulations. HadCM3B experiments were branched from the respective
131 HadCM3BL simulations after 4400 to 4900 years and integrated for a further 2950 years. Multiple ocean gateways in the
132 original paleogeography were widened to allow unrestricted ocean circulation and to guarantee the same gateway widths on
133 both the low and high-resolution ocean grids of HadCM3BL and HadCM3B, respectively. In addition, maximum water depths
134 in parts of the Arctic Ocean were reduced to improve numerical stability.

135 **INMCM**

136 The ocean temperature and salinity in the $\times 6$ simulation follow the idealised equations of the DeepMIP protocol¹², but with
137 equatorial surface temperatures lowered by 5 °C. The simulation was integrated for a total of 1150 years.

138 **IPSL**

139 A modified version of the idealised DeepMIP temperature and salinity equations¹², but with overall reduced temperatures,
140 was used to initialise the $\times 3$ simulation. The $\times 1.5$ simulation is branched from the $\times 3$ experiment after 1500 years. Both
141 simulations are run for a total of 4000 years. The ocean bathymetry around individual ocean straits has been manually adjusted

142 to guarantee the minimum gateway width necessary to allow throughflow.

143 ***MIROC***

144 All three simulations have been initialised with a modified version of the idealised DeepMIP temperature and salinity equations^{[12](#)},
145 with ocean temperatures globally reduced by 15 °C, and integrated for 5000 model years. The $\times 1$ and $\times 2$ experiments are new
146 and have not been included in the DeepMIP overview paper^{[13](#)}.

147 ***NorESM***

148 Initial ocean temperatures for the $\times 2$ simulation were used from a previous NorESM-L simulation^{[28](#)}, while salinities were set to
149 25.5 psu in the Arctic and 34.5 elsewhere. The $\times 4$ simulation was branched off after 100 model years, and both simulations have
150 been run for a further 2000 years. The NorESM simulations were performed with a different paleogeographic reconstruction
151 than the rest of the DeepMIP ensemble (Table 1).

152 **Data processing**

153 We use the raw output of the last 100 years of each of the 35 model simulations as input for our post-processing. For each
154 variable, we generate up to three netCDF output files to facilitate common analysis workflows. We always produce a `mean` file
155 representing either the monthly mean climatology or the annual mean averaged over the last 100 model years, depending on the
156 temporal resolution of the model output. In case of monthly mean output data, the `std` file contains the standard deviation over
157 the same averaging period for each month of the year and can be used for significance testing. Where feasible, we also store the
158 full monthly mean output of the last 100 model years as a `time_series` file to investigate temporal trends or interannual
159 variability.

160

161 Alongside this standard output, we provide a generic script to interpolate model fields from their native grids to a common
162 resolution for model intercomparisons. The processing workflow requires a local installation of the Climate Data Operator
163 (CDO) software^{[29](#)} for bilinear or nearest-neighbour interpolation for atmosphere and ocean variables, respectively. Example
164 output for commonly used variables (i.e., near-surface air temperature, sea surface temperature and total precipitation) on
165 a common $1^\circ \times 1^\circ$ grid is included in the database and can be directly used for analysis or to verify results of any local
166 postprocessing. The processing script is distributed as part the database (see Data Records section).

167 **Naming convention**

168 We employ a consistent naming convention for variables, directories, and file names across all models to simplify the
169 comparison of different models and to allow a scripted analysis of the entire database. The list of output variables is an
170 extended version of those proposed in the DeepMIP experimental design¹² and is shown in Tables 3-4. Variable names, units
171 and signs of fluxes follow the naming convention of the Coupled Model Intercomparison Project 6 (CMIP6) data request
172 (https://wcrp-cmip.github.io/WGCM_Infrastructure_Panel/CMIP6/data_request.html, last access: 18 October 2023). Consistent
173 standard names, long names and global attributes are directly added to the netCDF files following the Climate and Forecast
174 metadata conventions (CF³⁰) in version 1.8 (<http://cfconventions.org>, last access: 18 October 2023). All netCDF file have been
175 automatically tested for CF-compliance with the cf-checker utility (<https://github.com/cedadev/cf-checker>, last access: 18
176 October 2023) developed by the UK Met Office and the NCAS Computational Modelling Services (NCAS-CMS). Following
177 the CMIP and CF community standards will both increase user familiarity with the new database and will allow the integration
178 into existing analysis workflows and software. Each output variable is stored in a separate file according to the following
179 structure:

180 directory = deepmip-eocene-p1/<Family>/<Model>/<Experiment>/<Version>/<Averaging>/
181
182 filename = <Variable>_<Model>_<Experiment>_<Version>. <Statistic>.nc

183 where:

- 184 • <Family>, <Model> and <Experiment> are listed in Table 1 and Table 2, respectively
- 185 • <Variable> represents the first column in Tables 3-4
- 186 • <Statistic> is either mean (1 or 12 timesteps), std (12 timesteps), time_series (1200 timesteps) or omitted for
187 the time-independent boundary conditions
- 188 • the smaller mean and std files are stored in the <Averaging>=climatology directory and are separated from
189 the larger time_series files in the <Averaging>=time_series directory to enable more granular download
190 options

191 Storing all relevant information in the file name itself also allows new phases of coordinated DeepMIP simulations to be
192 integrated into a single database in the future. All output files will be uploaded to the CEDA Archive for long-term storage

193 after any potential changes arising from the peer-review process have been implemented. During peer-review, all files can be
194 anonymously accessed via [Google Drive](#).

195 **Web application**

196 In addition to depositing the database to the central CEDA repository, we also provide access to a subset of data through a new
197 web application available at <https://data.deepmip.org>. The website is designed to extract surface temperature and precipitation
198 for any user-defined location from all available model simulations and either visualise the results or download them for offline
199 use. All processing code is written in Python and bundled into a web application via the Streamlit library (<https://streamlit.io>;
200 last access: 29 September 2023). The code makes full use of the naming conventions described above and is therefore general
201 enough to serve as a template for further in-depth analysis. Detailed instructions on how the application and underlying code
202 can be used to extract subsets from the database are given in the Usage Notes section.

203 **Data Records**

204 The database will be deposited in the CEDA Archive, the UK national data centre for atmospheric and earth observation
205 research, and is currently available via [Google Drive](#). This dataset contains the following types of files:

- 206 • **model data:** The directory `deepmip-eocene-p1` contains all processed model output in CF compliant netCDF
207 format³¹, a self-describing community standard for storing gridded simulation data, with a total file size of 175.8 GB.
208 Directory and file structure follow the DeepMIP naming convention described above.
- 209 • **model READMEs:** Each <Family> top-level directory contains a single <Family>_README.md file that contains
210 detailed information about the model, the simulation setup, and output variables available in the respective subdirectories.
211 This ensures the downloaded database is sufficiently self-described and allows the addition of new models and simulation
212 results in the future. The Markdown files are also converted to the PDF format for convenience.
- 213 • **validation_tables directory:** PDF files with tables of available output variables for each model, grouped by atmosphere
214 and ocean variables and the respective DeepMIP experiments. The tables also include global minimum/mean/maximum
215 values of all fields for a first-order quality check (see Technical Validation section for details).
- 216 • **scripts directory:** Collection of code to interpolate model data to a common grid (`regrid_database_v1.0.sh`),
217 create validation tables of available data (`plot_z-scores_v1.0.py`) and Python dictionaries containing available
218 DeepMIP models, experiments and variables to support scripted analysis of the database (`deepmip_dicts_v1.0.py`).

219 **Technical Validation**

An earlier version of the database has already been used in a number of publications^{13–15,17–22} to assess the scientific validity of the model simulations, both in terms of model-model and model-data comparisons. In this section, we verify the internal consistency of the database, ensuring that the naming convention has been applied correctly and that the resulting variable names, units and fluxes are consistent across all models. To do this, we automatically parse all `mean` and `time_series` files in the database for any given experiment, interpolate them to a common grid, calculate the global mean, minimum and maximum values and compare these values across all models. We use annual mean fields for the validation of `mean` files and the last 12 available months of the `time_series` files. For variables with multiple vertical levels (see Tables 3–4), we select the vertical index nearest to the 500 hPa pressure level or 1000 m depth for atmospheric and ocean data, respectively. Example tables for atmospheric and ocean mean variables from the $\times 3$ simulations are shown in Fig. 1 and Fig. 2, tables for all other experiments as well as for `time_series` files are uploaded to the online database and web application. This testing procedure simulates a standard analysis workflow and is able to detect any deviations from the expected DeepMIP naming convention, while the resulting tables provide a visual overview of available model fields for each experiment. We further calculate the median and standard deviation for each variable and metric across all available models (i.e. for each row in the table) to flag potential outliers that may arise due to inconsistent units or different directions of energy or mass fluxes. For this, we calculate a z-score for each model, variable and statistic which quantifies the number of standard deviations an individual model statistic is above or below the ensemble median. We use the ensemble median instead of the mean as the reference point to reduce the influence of potential outliers in our small sample sizes and calculate the adjusted z-scores as:

$$z = \frac{x - M}{\sigma} \quad (1)$$

220 where z is the computed z-score, x is the individual model value, M is the median across all available models for the respective
221 variable and statistic (i.e., across each table row), and σ is the standard deviation across the ensemble. A z -score > 3 is
222 commonly used as a cut-off to identify outliers in a distribution. Due to the small sample sizes ($N \leq 9$) the z-score threshold
223 was not used to exclude any data from the database, but rather to find and resolve inconsistencies in the data processing between
224 the models. In the final database, all model fields are within ± 3 standard deviations around the respective ensemble median,
225 although we note that the small sample sizes allow only an indicative analysis. The Python processing code is included in the
226 online database (see Data Records section) and can be used to develop a custom analysis workflow or to validate any regridding

227 and global averaging performed by the user.

228 Usage Notes

229 We present two primary routes to access the database, either via downloading the netCDF files for local processing or via an
230 interactive website for online model-data comparisons.

231 netCDF repository

232 First, processed netCDF files for all simulations will be available from the CEDA Archive. The full directory structure can be
233 accessed via the browser and files can be downloaded via HTTP, Wget, FTP or OPeNDAP. This allows easy access to the data
234 via the browser, as well as scriptable interfaces for bulk downloading. The OPeNDAP (Open-source Project for a Network Data
235 Access Protocol) protocol allows the remote subsetting and exploration of datasets directly in Python, R, IDL, and Matlab.
236 THE CEDA Archive website (<https://help.ceda.ac.uk/article/99-download-data-from-ceda-archives>; last access: 29 September
237 2023) gives an up to date overview of all available access options.

238

239 Interactive web application

240 Second, simulated surface temperatures and precipitation from any location can be extracted, visualised and downloaded at
241 <https://data.deepmip.org>. This allows model-data comparisons via a simple user interface without the need to download the
242 netCDF files locally. The sidebar of the web application can be used to choose between three different analysis pages:

- 243 1. **Extract local model data:** Finds the model data closest to a user-specified site (see example in Fig. 3). The minimum
244 inputs are the modern location of the site and the variable of interest (either near-surface air temperature, sea surface
245 temperature, or total precipitation). The application will automatically reconstruct the site's EECO paleo-position on both
246 the mantle²³ and paleomagnetic²⁴ reference frames and extract the respective monthly and annual mean simulation data
247 from the closest grid point for all models in the database. Model data is interpolated to a common $1^\circ \times 1^\circ$ grid (see Data
248 processing section for details) prior to the data selection to eliminate the influence of different model resolutions on the
249 results. In the end, the ensemble means for each experiment are calculated and the results are listed in an interactive table.
250 Data can be downloaded in CSV, Excel or JSON format for direct import into spreadsheets for further offline analysis.
251 The extraction can be performed for a single site or a list of locations and all sites from the DeepMIP proxy database²
252 are pre-loaded and available for comparison with the simulation results. Furthermore, the underlying Python functions

253 `get_paleo_locations()` and `get_model_point_data()` are available in the `deepmip_modules.py` file
254 of the application repository for reuse in any custom analysis. The `get_paleo_locations()` function uses the
255 paleolocation lookup fields provided in the experimental design paper¹² to find the respective early Eocene locations
256 for a list of modern latitude/longitude pairs, using both the mantle²³ and paleomagnetic²⁴ reference frames. Results are
257 saved in a Pandas DataFrame which can be directly passed to `get_model_point_data()` to extract the nearest
258 model data for all reconstructed locations.

259 **2. Plot local model data:** Visualises the extracted results and optionally compares them to proxy reconstructions (see
260 example in Fig. 4). Available visualisations include line plots of the annual cycle at the user-specified location, grouped
261 by the various DeepMIP CO₂ levels (Fig. 4a), and a scatter plot of all simulated annual mean values against the respective
262 GMSTs or CO₂ concentrations of the model simulations. (Fig. 4b). The latter plot type can be useful to compare the
263 sensitivity of the model results at the local site against global climate signals. The simulated monthly and annual mean
264 model results can be visually compared against a local proxy reconstruction, either by manually specifying the mean and
265 standard deviation of the proxy data or by loading the respective values for locations from the DeepMIP proxy database².
266 The user can zoom and pan within the interactive figures and download them in PNG and SVG format.

267 **3. Map sites and boundary conditions:** Plots paleogeographic maps of the chosen site. The user can choose between a
268 global map indicating the location of the study site or regional maps of the bathymetry, orography and land-sea mask on
269 the various native model grids (Fig. 5). The latter can help with the interpretation of the model-data comparison result,
270 e.g. by visualising local grid resolutions and associated intermodel differences in the representation of mountain ranges
271 or ocean gateways.

272 **How to cite the database**

273 This Data Descriptor paper should be cited whenever any netCDF files from the database or results from the web application
274 are reused in a publication. In addition, the user might want to cite the previously published overview of simulated large-scale
275 climate features¹³ or the DeepMIP-Eocene experimental design¹², as appropriate.

276 **Code availability**

277 Processing code to interpolate model fields and to create the validation overview tables is included in the online database,
278 currently available via [Google Drive](#). The code for the web application is available at <https://github.com/sebsteinig/deepmip>.

347 **Acknowledgements**

348 Sebastian Steinig and Daniel J. Lunt acknowledge funding from the NERC SWEET grant (grant no. NE/P01903X/1). Daniel J.
349 Lunt also acknowledges funding from NERC DeepMIP grant (grant no. NE/N006828/1) and the ERC (“The greenhouse earth
350 system” grant; T-GRES, project reference no. 340923, awarded to Rich Pancost). The CESM project is supported primarily by
351 the National Science Foundation (NSF). This material is based upon work supported by the National Center for Atmospheric
352 Research, which is a major facility sponsored by the NSF under Cooperative Agreement No. 1852977. MIROC simulations
353 were supported by funding from KAKENHI grant no. 17H06104 and 17H06323. Gordon. N Inglis was supported by a Royal
354 Society Dorothy Hodgkin Fellowship (DHF\R1\191178) and NERC Large Grant (NE/V018388/1). Agatha de Boer and David

355 Hutchinson acknowledge support from Swedish Research Council Grant 2016-03912 and FORMAS grant 2018-0162. The
356 GFDL simulations were performed using resources from the Swedish National Infrastructure for Computing (SNIC) at the
357 National Supercomputer Centre (NSC), partially funded by the Swedish Research Council Grant 2018-05973.

358 **Author contributions statement**

359 The model simulations and individual post-processing were carried out by JZ and CJP (CESM), IN and GK (COSMOS), DKH
360 and AMdB (GFDL), SS and DJL (HadCM3), PM and EMV (INMCM), JBL and YD (IPSL), WLC and AAO (MIROC), and
361 ZZ (NorESM). DE, GNI and ANM provided input on the web application and proxy data implementation. SS compiled the
362 final database and developed the web application. SS wrote the manuscript with contributions from all authors.

363 **Competing interests**

364 The authors declare no competing interests relevant to this study.

cl	Percentage Cloud Cover	%	level×time×lat×lon
hus	Specific Humidity	1	level×time×lat×lon
ta	Air Temperature	K	level×time×lat×lon
ua	Eastward Wind	$m\ s^{-1}$	level×time×lat×lon
va	Northward Wind	$m\ s^{-1}$	level×time×lat×lon
wap	Omega (=dp/dt)	$Pa\ s^{-1}$	level×time×lat×lon
zg	Geopotential Height	m	level×time×lat×lon
orog	Surface Altitude	m	lat×lon
sftlf	Percentage of the Grid Cell Occupied by Land	%	lat×lon

Table 4. Ocean output variables included in version 1.0 of the database. Naming conventions follow the CMIP6 data request.

Name	Long Name	Units	Dimensions
tos	Sea Surface Temperature	°C	time×lat×lon
siconc	Sea-Ice Area Percentage (Ocean Grid)	%	time×lat×lon
mlotst	Ocean Mixed Layer Thickness Defined by Sigma T	m	time×lat×lon
zos	Sea Surface Height Above Geoid	m	time×lat×lon
hfds	Downward Heat Flux at Sea Water Surface	W m ⁻²	time×lat×lon
wfo	Water Flux Into Sea Water	kg m ⁻² s ⁻¹	time×lat×lon
tauuo	Sea Water Surface Downward X Stress	N m ⁻²	time×lat×lon
tauvo	Sea Water Surface Downward Y Stress	N m ⁻²	time×lat×lon
msftbarot	Ocean Barotropic Mass Streamfunction	kg s ⁻¹	time×lat×lon
msftmz	Ocean Meridional Overturning Mass Streamfunction	kg s ⁻¹	time×depth×lat
so	Sea Water Salinity	0.001	depth×time×lat×lon
thetao	Sea Water Potential Temperature	°C	depth×time×lat×lon
uo	Sea Water X Velocity	m s ⁻¹	depth×time×lat×lon
vo	Sea Water Y Velocity	m s ⁻¹	depth×time×lat×lon
wo	Sea Water Vertical Velocity	m s ⁻¹	depth×time×lat×lon
difvmo	Ocean Vertical Momentum Diffusivity	m ⁻² s ⁻¹	depth×time×lat×lon
difvtrbo	Ocean Vertical Tracer Diffusivity Due to Background	m ⁻² s ⁻¹	depth×time×lat×lon
deptho	Sea Floor Depth Below Geoid	m	lat×lon

User input

Number of sites to extract data for:

Single site Multiple sites

Select the present-day location of your site and the variable you are interested in.

modern latitude of site	modern longitude of site	variable	OPTIONAL: name of site
52.4	- + 11.8	- + sea surface temperature	Store Bælt, Denmark

GET MODEL DATA

⚠ Warning: Land points for sea surface temperatures (SSTs) are filled by a nearest-neighbour lookup to facilitate the intermodel comparison in coastal regions. Please make sure that you selected a marine/coastal location by checking the model land-sea masks on the [Paleogeography page](#).

Figure 3. Example user input and extracted model data for a single site in the web application.

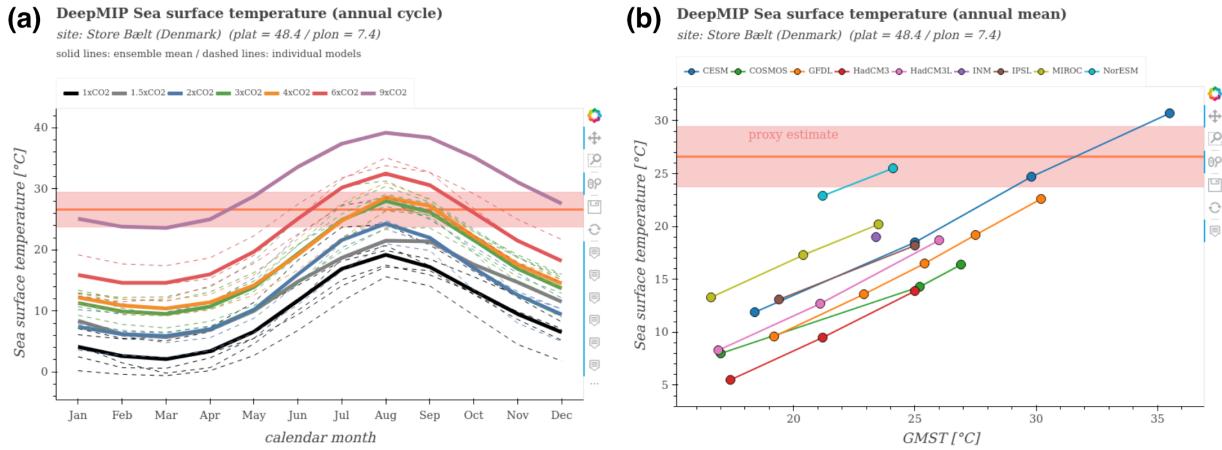

Figure 4. Example graphical output of the web application for the model-data comparison of the Store Bælt (Denmark) site defined in Fig. 3. (a) Simulated annual cycle of sea surface temperatures at the respective grid point closest to the reconstructed paleoposition of the site. Solid lines show the ensemble mean for each CO₂ concentration with individual models represented by the dashed lines. (b) Scatter plot of the simulated annual mean sea surface temperature at the proxy site compared to the global mean surface temperature of the respective simulation. Lines connect results of the same model. Reconstructed proxy temperature is based on the TEX₈₆ paleothermometer².

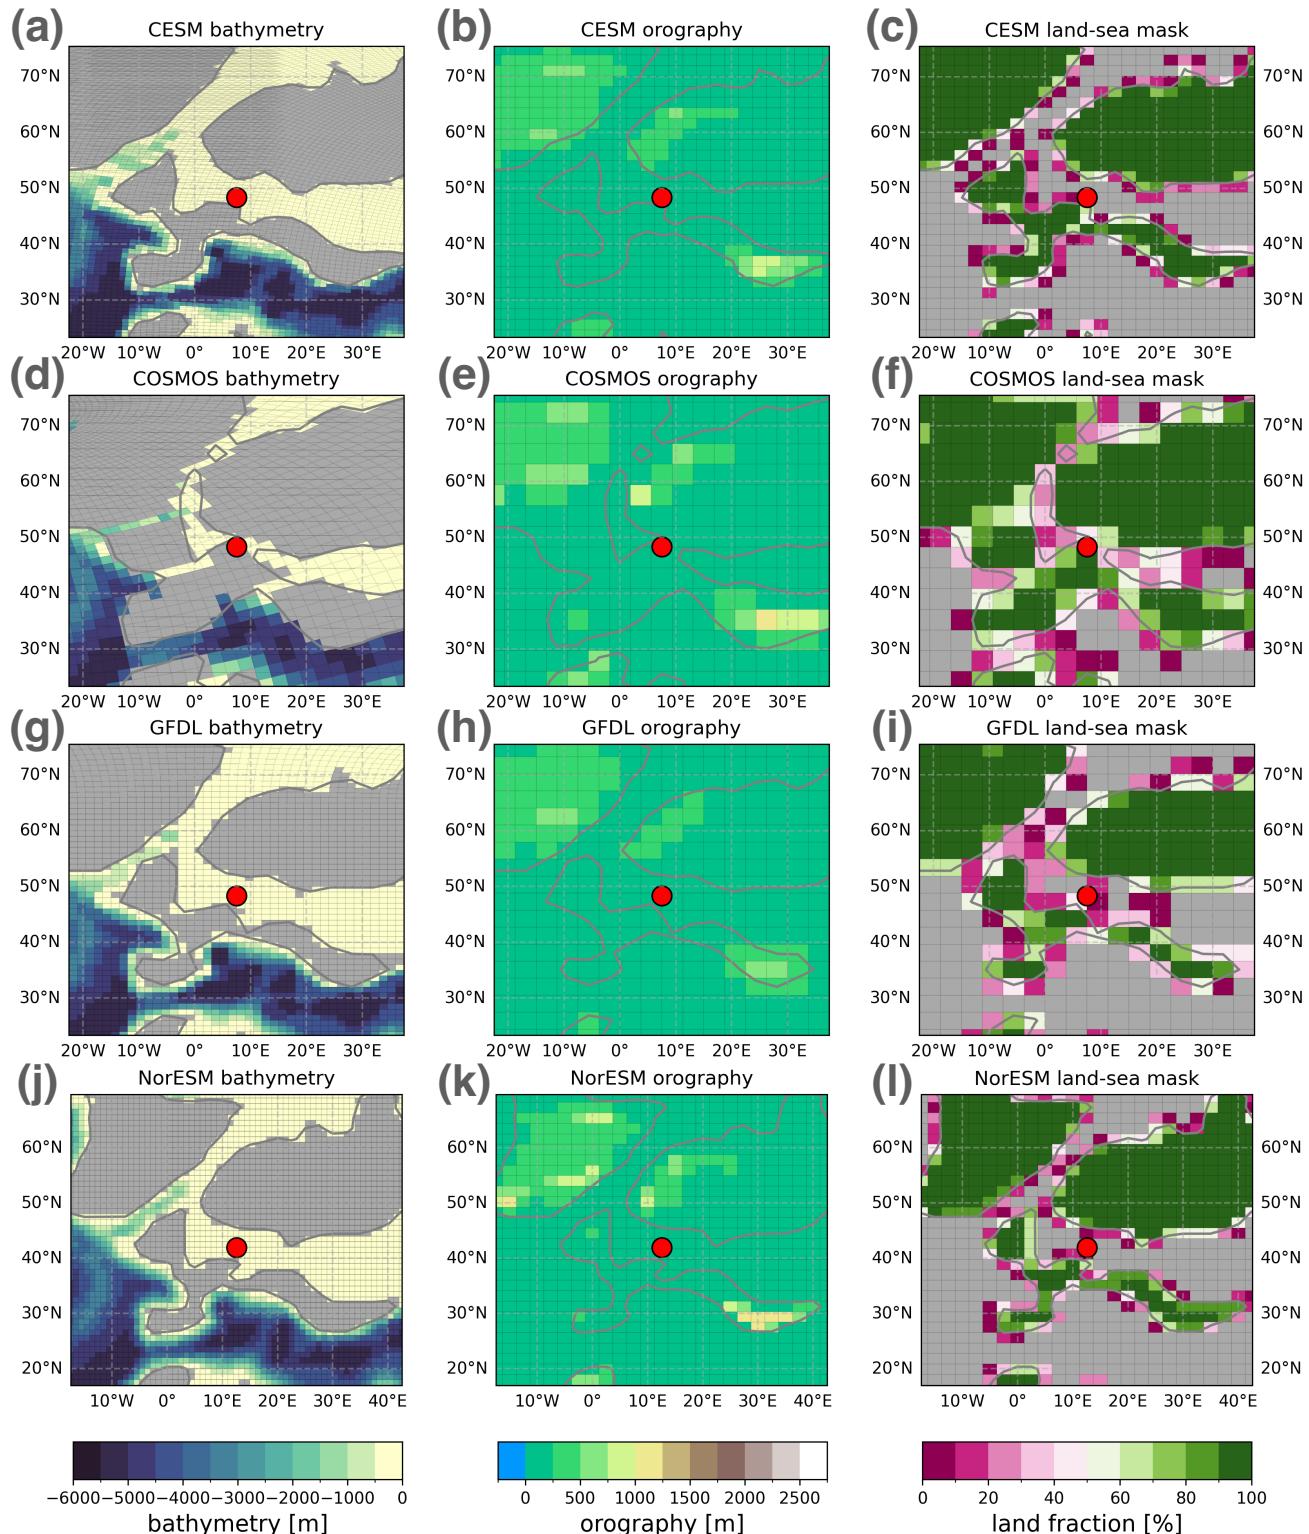

Figure 5. Maps of local boundary condition differences between some of the models around the the Store Bælt (Denmark) site defined in Fig. 3 produced by the web application. The reconstructed paleoposition of the site (red dot) represents a land point in COSMOS (panel d-f) and ocean points in the other models. Note the different paleogeographic reconstruction used in NorESM (panel j-l).
